## Lecture - Signal Encoding Techniques

📅 2025-09-29

🕒 11:00

👤 Asim

There is a deck of slides on Moodle introducing this module's structure & assessments, etc.

### 1.1 Introduction to Concepts

#### 1.1.1 Computer Networks

##### Definitions

**Computer Network** A system that connects two or more computing devices for transmitting and sharing information (data)

There are a number of different activities which can be done on a network:

- Watching Videos
- Playing Games
- Sending and Receiving Messages (including not just text)
- Paying Bills

The core function of the network is to exchange data between interconnected devices.

#### 1.1.2 Data & Signals

Data is the information which is transmitted between devices on the network. The type of the data depends on the context and may include:

- Video
- Audio
- Text
- Images

For data to be able to travel on the network - it has to be converted into digital or analog format. Once in either of these formats, the resultant data is known as *signals*.

##### Definitions

**Signal** Electromagnetic Waves that carry data

**Analog Signal** are signals which vary smoothly over time and have no fixed point to change at and don't have fixed levels

**Discrete Signal** are signals which maintain constant level for some time then then change to another constant level

**Digital Signal** are signals which have only two levels - one high to indicate on, or 1, and one

low to indicate off, or 0

Figure 1.1: Analog Signal

Figure 1.2: Discrete Signal

Figure 1.3: Digital Signal

## 1.2 Data Communications

Within a Data Communications Network - the data will convert between Digital and Analog data at various points. A *modem* may be used to complete this conversion.

Figure 1.4: Block Diagram of Example Data Communications Signal Chain

In the above diagram, the *workstation* provides the *modem* with a digital signal. The modem then converts this digital signal into an analog signal which can be transmitted across the *Public Telephone Network* that uses analog signals. The receiving *modem* converts the signal to a digital format which the *server* receives.

In saying this, however, there are some devices which still work entirely on analog or digital signals. For example, the analog telephone network including the switching and transmission is entirely analog. There is also the inverse whereby there are entirely digital signals are processed.

### 1.3 Digital-To-Digital Signal Encoding

Digital signals are transmitted such that an individual value is transmitted for a defined period of time called the *bit duration*. The *bit duration* is known to both the sender and receiver, allowing the receiver to correctly interpret the transmitted signal which the sender will always transmit at the beginning of the bit duration. We assume the sender and receiver are synchronised and therefore the clock or is not transmitted.

The move between two different defined voltages within the transmission is called the *transition*.

As digital signals are discrete (meaning there are defined, absolute data levels) encoding a digital signal as another digital signal is considerably simpler as we don't have to convert one data level to another.

#### 1.3.1 Nonreturn to Zero Level (NRZ-L)

This method only has two levels of data transmitted. It works through mapping the high data level (1) and low data level (0) to a signal level:

- 0 - represented by a high level signal
- 1 - represented by a low level signal

Figure 1.5: Example of NRZ-L Encoding using 110010

#### 1.3.2 Nonreturn to Zero Inverted (NRZ-I)

This method is similar to NRZ-L in that it uses two levels of data transmitted: high and low. However it uses the transitions to define the data being transmitted. Looking at the bit following a transition point, even if there is no transition present:

- Where there is a transition (regardless of 1 to 0, or 0 to 1): the following signal bit is transmitted as is high
- Where there is not a transition (regardless of 1 to 1, or 0 to 0): the following signal bit is transmitted as low

Figure 1.6: Example of NRZ-I Encoding using 110010

### 1.3.3 Bipolar-AMI

This has three signal levels: high, zero, and low. It works through setting the signal based on the bit to be transitioned to:

- 0 - represented by transmitting zero
- 1 - represented by alternating high and low values, regardless of if there is a 0 value in the middle

Figure 1.7: Example of Bipolar-AMI Encoding using 110010

### 1.3.4 Pseudoternary

This has three signal levels: high, zero, low. It works through setting the signal based on the bit to be transmitted:

- 0 - represented by alternating high and low values, regardless of if there is a 1 value in the middle of them
- 1 - represented by transmitting zero value

This is the inverse of Bipolar-AMI.

Figure 1.8: Example of Pseudoternary Encoding using 110010

### 1.3.5 Manchester

This has two signal levels: high and low. It works through having up-to two transitions per interval:

- 0 - represented by a transition from high to low in the middle of the interval (which for successive zeros will require a low-to-high transition at the start of the interval)
- 1 - represented by a transition from low to high in the middle of the interval (which for successive ones will require a high-to-low transition at the start of the interval)

Figure 1.9: Example of Manchester Encoding using 110010

### 1.3.6 Differential Manchester

This has two signal levels: high and low. It works by always transitioning in the middle of the interval and then examining the transition at the beginning of the interval:

- 0 - represented by a transition at the beginning of the interval
- 1 - represented by no transition at the beginning of the interval

Figure 1.10: Example of Differential Manchester Encoding using 110010

### 1.3.7 Multi-Level Transmit 3 (MLT-3)

This uses three different signal levels: low, zero and high. It works by cycling through these states based on the bit to be transmitted:

- 0 - remain on the current signal level (regardless of signal level value)
- 1 - move to the next state in the cycle of signal levels (high - zero - low - zero repeat)

Figure 1.11: Example of MLT-3 Encoding using 110010

## 1.4 Electromagnetic Waves

Electromagnetic waves are the digital representation of an analog signal. They are considered to be smooth as they don't have fixed values. The key properties of any EM wave are as follows: Amplitude, Phase, Wavelength & Frequency.

Figure 1.12: Electromagnetic Wave showing Amplitude ( $A$ )

Figure 1.13: Electromagnetic Wave showing Phase (dashed)

Figure 1.14: Electromagnetic Wave showing Wavelength ( $\lambda$ )

Figure 1.15: Electromagnetic Wave showing increased frequency (dashed)

### 1.4.1 Carrier Waves & Modulation

#### Definitions

**Carrier Wave** a continuous, periodic waveform that carries no information

A *carrier wave* is modified by an information-bearing signal to convey information. The modification can be by either changing: its amplitude, frequency, phase, or some combination of the three. The process of modifying a carrier wave is called *modulation*.

## 1.5 Digital Data, Analog Signals

There are many examples of where digital data has to be transmitted through an analog medium. The most well-known of which being the public telephone network. This is designed to transmit voices, within the frequency of 300 to 3400 Hz; therefore a problem is presented when a digital device is connected to the network. This problem is overcome by connecting the digital device to a Modem (Modulator-Demodulator) which converts digital data to analog signals and the other way around.

There are a number of different methods which can be used to convert digital data onto an analog signal. These methods employ a carrier wave for the digital data to be modulated onto. For the subsequent examples - it's assumed the carrier wave is a sine wave.

### 1.5.1 Amplitude-Shift Keying

Amplitude-Shift Keying (ASK) modulation works by modulating the digital signal onto the amplitude of the carrier wave. Meaning that the amplitude of the carrier wave is increased for a digital 0 and decreased for a digital 1.

Figure 1.16: Example of ASK Modulation

### 1.5.2 Frequency-Shift Keying

Frequency-Shift Keying (FSK) modulation works by modulating the digital signal onto the frequency of the carrier wave. This means that the frequency of the carrier wave is increased for a digital 1 and decreased for a digital 0.

The sender and receiver may use different frequencies to allow full-duplex transmissions on the same channel. It is less susceptible to errors than ASK modulation is. FSK can be used for higher frequencies (3 - 30 MHz), radio and Local Area Network transmissions. It can also support Multiple Levels in MFSK.

The *bandwidth* of the transmission is the difference between the frequency of the high frequency (representing a 1) and the low frequency (representing a 0). Different frequency carrier waves will be used for sending and receiving on the same line.

The most common form of FSK is Binary FSK (BFSK) in which the two binary values are represented by two different frequencies near the carrier frequency:

- 0 - represented by  $A \cos(2\pi f_1 t)$
- 1 - represented by  $A \cos(2\pi f_2 t)$

Figure 1.17: Example of BFSK Modulation

### 1.5.3 Phase Shift Keying

Phase Shift Keying (PSK) Modulation works by modulating the digital signal onto the phase of the carrier wave. This means that the phase of the carrier wave is adjusted to represent digital 0 and digital 1, respectively. There are two different types of PSK studied here.

#### 1.5.3.1 Binary Phase Shift Keying

Binary PSK (BPSK) works by using two phases to represent two different binary digits (0 and 1) and shifting between them:

- 0 - represented by the sine wave  $A \cos(2\pi ft + 180)$  which equals the sine wave  $-A \cos(2\pi ft)$
- 1 - represented by the sine wave  $A \cos(2\pi ft)$

Figure 1.18: Example of BPSK Modulation

#### 1.5.3.2 Differential Phase Shift Keying

Differential PSK (DPSK) works by referencing the previous bit in the current bit transmitted. DPSK removes the need for an accurate local oscillator phase at the receiver which is matched with the transmitter, because so long as the preceding phase is received correctly - the phase reference is accurate.

- 0 - send a signal similar to the previous one
- 1 - send a signal with phase shift as compared to the previous one

Figure 1.19: Example of DPSK Modulation

### 2.1 Communication Channels

There are two different types of Communications Channels (also sometimes referred to as *Communication Media* or *Transmission Media*).

#### Definitions

**Guided Media** Wired (Bounded) Media (i.e Twisted Pair, Coaxial, Fibre Optic)

**Unguided Media** Wireless Media (i.e. Microwave, Radio Wave. Cellular, Infrared, Satellite)

Within Guided Media, the electromagnetic waves are guided along a physical path. The medium can be considered to be *point-to-point* if it provides a direct link between two devices and those two devices are the only devices sharing the medium.

Unguided media is the opposite - where the electromagnetic waves are not guided through any physical containment, rather they transmit through air, vacuum or seawater.

The term *Direct Link* is used to refer to a transmission path where the signal is transmitted directly from sender to receiver without any intermediate devices. This can apply to both guided and unguided media. A *multipoint guided configuration* is a configuration such that more than two devices share the same medium.

A transmission may be simplex, half duplex or full duplex.

#### Definitions

**Simplex** a transmission in which signals are only transmitted in one direction; one station is the transmitter and the other is the receiver.

**Half-Duplex** a transmission in which both stations can transmit and receive but only one can transmit at one time therefore

**Full-Duplex** a transmission in which both stations can transmit and receive at the same time; which requires a medium is required for signals to be transmitted in both directions at the same time

In a full-duplex transmission system there may sometimes be an overlap in the frequency ranges used for each direction of transmission. This is sometimes acceptable and sometimes not - depending on the application. In any case, the overlap would be at the very edges of the frequency range; however this would still cause some interference.

There is a diagram detailing the frequencies used for different unguided transmissions available both in the slides on Moodle & in the textbook on page 109.

## 2.2 Interference and Noise

Often with transmissions - our signal may be interrupted in some way. This will alter the signal being transmitted which could change the data it represents - therefore garbling the resultant wave. Often this interference will come from *noise*.

### Definitions

**Interference** The combination of two or more electromagnetic waveforms to form a resultant wave in which the displacement is either reinforced or cancelled

**Noise** An unwanted signal which is combined with desired signal

Figure 2.1: Constructive Interference

Figure 2.2: Destructive Interference

As we can see in the above figure, where we have two waves which are of the same phase interfering with each other - they will *interfere constructively* to increase the amplitude of the resultant wave. However where two waves in opposite phase interfere with each other - they will *interfere destructively* to effectively cancel each other out and the resultant wave has no amplitude.

For any data transmission, the received signal will consist of the transmitted signal, modified by the various distortions used by the transmission system, plus additional unwanted signals that are inserted somewhere between transmission and reception (which is referred to as *noise*).

Noise can be divided into four categories:

- Thermal Noise
- Intermodulation Noise
- Crosstalk
- Impulse Noise

## 2.3 Basic Definitions

### Definitions

**Data Rate** The rate, in bits per second (bps), at which data can be communicated

**Error** The reception of a 1 where 0 was transmitted, or the reception of a 0 when a 1 was transmitted

**Error Rate** The rate at which errors occur

**Frequency Bandwidth** The difference between the upper and lower frequencies in a continuous band of frequencies

**Channel Capacity** The maximum rate at which information can be transmitted through a communication channel

**Signal to Noise Ration (SNR)** The ratio of the signal power to the noise power, measured in Decibels  $10 \log_{10} \frac{\text{signal power}}{\text{noise power}}$

The *Channel Capacity* can be calculated using:

$$C = 2B \log_2 M$$

Where  $C$  is the channel capacity;  $B$  is the bandwidth;  $M$  is the signal or voltage levels.

The Nyquist Bandwidth Theory stipulates that if the rate of signal transmission is  $2B$  then a signal with frequencies no greater than  $B$  is sufficient to carry the signal rate. The converse is also true. This limitation is due to the effect of intersymbol interference, which is produced by delay distortion. This is in essence based on the Nyquist Sampling Theorem (flashback to A-Level Electronics).

From this we can see that permitting all other things being equal, when we double the bandwidth - we double the error rate. The error rate then only gets worse as we increase the data rate because a higher data rate will mean the bits are shorter so more bits are affected by a given pattern of noise. Mathematician *Claude Shannon* tied these into a formula:

$$C = B \log_2(1 + SNR)$$

Where  $C$  is the capacity of the channel in bps and  $B$  is the bandwidth of the channel in Hertz.

## 2.4 Multiplexing

### Definitions

**Multiplexing** A technique that allows the simultaneous transmission of multiple signals through the same channel or link; several signals are combined into a single composite signal

### 2.4.1 Frequency Division Multiplexing

In Frequency Division Multiplexing (FDM), the different message signals are modulated onto different carrier frequencies. This then means the signals being transmitted are separate from each other in the frequency domain. These modulated signals are then combined together to form the composite signal and this signal is sent over the shared medium or channel. To avoid the interference between the different message signals, a guard band is also kept between the message signals.

On the transmitter end, the signals to be transmitted are modulated onto the different carrier frequencies. Then on the receiver end - the frequencies first pass through a Band Pass Filter (definition not required for this module), then through the demodulator, then finally through a low pass filter (again, definition not needed in this module). The band pass filter is used to separate the specific

signal from the composite signal, and the low pass filter is used to filter out the higher frequencies introduced as part of the FDM process.

Graph of FDM?

### 2.4.2 Time Division Multiplexing

In Time Division Multiplexing (TDM), the channel is divided into several time slots, and each signal allocated during its time slot. As a result - several signals share the channel without interfering with each other.

Graph of TDM?

## 2.5 Spread Spectrum

When transmitting our analog signals (whether these originated as digital or analog), we can spread the signal over a wider bandwidth to avoid jamming and frequency interception.

Spread Spectrum is a technique used by military and intelligence applications which is also used in Wireless and Cordless networks. There are a number of different techniques which can be used, we will explore 3 of them.

### Definitions

**Pseudorandom Noise (PN)** is a deterministic sequence of bits which satisfies one or more of the standard tests for statistical randomness while being repeatable after a period

### 2.5.1 Frequency Hopping Spread Spectrum

In Frequency Hopping Spread Spectrum (FHSS), the signal is broadcast over a number of different radio frequencies, and the frequency used is changed at fixed intervals which are generally extremely short (i.e.  $1ms$ ). The receiver will hop between the different frequencies used in sync with the transmitter.

If the transmission is compromised, then the attacker would only hear unintelligible blips of the transmission. It would also thwart attempts to jam the signal as the attacker would only be able to block a few bits of the signal.

FHSS transmission systems tend to work with the binary data being fed into a modulator using a digital-to-analog encoding scheme (for example FSK or BPSK). The resultant signal is centred in a frequency. A PN source serves as an index into a table of frequencies; this is the spreading code. Each  $k$  bits of the PN source specifies one of the carrier frequencies. At each pre-agreed interval, a new carrier frequency is selected. This frequency is then modulated by the signal produced from the initial modulator to produce a new signal with the same shape, but now centred on the selected carrier frequency.

On reception - the spread spectrum signal is demodulated using the same sequence of frequencies derived from the PN source, and then demodulated to produce the output data.

### 2.5.2 Direct Sequence Spread Spectrum

Direct Sequence Spread Spectrum (DSSS) works by encoding a single bit to be transmitted (i.e. 1) as a multi-bit sequence (i.e. 0110) using a spreading code. The *spreading code* spreads the signal across a wider frequency band in direct proportion to the number of bits used. Which means that a 4-bit

spreading code spreads 1-bit of signal across a frequency band which is 4 times greater than a 1-bit spreading code. Of course, it doesn't have to be a 4-bit spreading code; it could be 10-bit or 20-bit.

A common method for encoding DSS is to combine the digital data input signal with a *Pseudorandom Noise (PN)* sequence (the individual bits within are called *chips*). The combined output signal is then referred to as a *chip sequence*.

In reality, this encoding process works by combining the digital data input signal with the Chip Sequence using an Exclusive Or (XOR) operation.

$$0 \oplus 0 = 0$$

$$0 \oplus 1 = 1$$

$$1 \oplus 0 = 1$$

$$1 \oplus 1 = 0$$

This produces a *combination bit stream* which has the data rate of the spreading code sequence, so therefore has a higher bandwidth than the information stream.

Finish the DSSS encoding graph diagram. Commented out in this document.  
Alternatively - add written out example?

### 2.5.3 Code Division Multiple Access Spread Spectrum

*Code Division Multiple Access* (CDMA) is a multiplexing technique used with spread spectrum.

It works taking our data signal with a bit-rate  $R$  and assigning a unique code of  $n$  chips according to the Walsh Matrix. Then, if the user  $k$  sends a 1 - the transmitter sends the chip code  $ck$ ; alternatively if the user  $k$  sends a 0 - the transmitter sends the chip code  $\bar{c}k$  (which is represented in this module with as  $c'k$ ).

Add Walsh Matrix derivations.

The chip codes of all users will add up into a bipolar signal  $D$ . The receiver performs the decoding function for user  $k$ , for example, by the cartesian product  $D \times ck$ . If  $D \times ck = n$  (the number of bits in the chip code), then bit 1 is received; else if  $D \times ck = -n$  then bit 0 is received.

#### Example: CDMA

If we take the following users to have the following Chip Codes:

- User A Chip Codes:  $(-1, -1, -1, -1)$
- User B Chip Codes:  $(-1, +1, -1, +1)$
- User C Chip Codes:  $(-1, -1, +1, +1)$
- User D Chip Codes:  $(-1, +1, +1, -1)$

#### Case 1

User A sends 1, user B sends 1, user C sends 1, and user D sends 0 (represented as -1).

We sum their chip codes, for A, B, and C - these are as specified above; however for D we need to invert the chip codes because D is transmitting a 0 (-1).

$$\begin{aligned} A + B + C + D' &= (-1, -1, -1, -1) + (-1, +1, -1, +1) + (-1, -1, +1, +1) + (+1, -1, -1, +1) \\ &= (-2, -2, -2, 2) \end{aligned}$$

The receiver will receive this and perform an inner product multiplication using the Chip Code

of A.

$$\begin{aligned}f &= (-2, -2, -2, 2) \times (-1, -1, -1, -1) \\&= (-2 \times -1) + (-2 \times -1) + (-2 \times -1) + (2 \times -1) \\&= 2 + 2 + 2 - 2 \\&= 4\end{aligned}$$

Which therefore confirms that A is sending a bit 1.

**Case 2**

User A sends 0 (-1), user B sends 1, user C sends 1, and user D sends 0 (-1).

We sum their chip codes, this time inverting A and D because they're transmitting 0s.

$$\begin{aligned}A + B + C + D' &= (+1, +1, +1, +1) + (-1, +1, -1, +1) + (-1, -1, +1, +1) + (+1, -1, -1, +1) \\&= (0, 0, 0, 4)\end{aligned}$$

Then we can find what the receiver decodes using A's chip code.:

$$\begin{aligned}f &= (0, 0, 0, 4) \times (-1, -1, -1, -1) \\&= (0 \times -1) + (0 \times -1) + (0 \times -1) + (4 \times -1) \\&= 0 + 0 + 0 - 4 \\&= -4\end{aligned}$$

As this results to  $-n$  (remembering  $n$  is the length of the users chip codes) - we know that A transforms to bit 0.

## Lecture - Security

📅 2025-10-13

🕒 11:00

👤 Asim

### 3.1 Security Requirements

Within *Network Security* there are three important requirements. The three requirements work together to ensure that network transmissions are of a good security standard.

#### Definitions

**Confidentiality** Ensuring that only authorised parties can read the message; therefore restricting unauthorised third parties from accessing it

**Integrity** Ensuring that the transmitted message is exactly the same as the received message and that only authorised parties can modify, delete, or reply to the message

**Availability** Ensuring the message is available on demand to authorised parties only

### 3.2 Attack Types

There are two main types of attack used.

#### Definitions

**Passive Attacks** Threat Actors analyse the traffic or read message content

**Active Attacks** Threat Actors modify the message content, deny the service to a request, replay to a message and masquerade (pretend to be a different entity)

We can attempt to overcome the threats using cryptography to encrypt the message on the transmitter's side, and then ensure that only the designated recipient can decode the message.

The message we want to encrypt, known as the *plaintext*, is transformed by a function that is parametrised by a *key*. The output of the encryption process, known as the *ciphertext*, is then transmitted. If this ciphertext is intercepted by the threat actor, they are unable to directly interpret it as they do not know what the key used in the encryption process was. However, it may be possible for the threat actor to crack the cipher depending on the encryption method used.

There is a standard notation for the plaintext, ciphertext and keys.  $C = EK(P)$  is used to represent the encryption,  $E$  of the plaintext,  $P$  using the key,  $K$  which results in the ciphertext,  $C$ . The decryption is defined as  $P = DK(C)$  where the plaintext,  $P$ , is the result of applying the decryption,  $D$ , with the key,  $K$ , on the ciphertext,  $C$ .

### 3.3 Encryption Techniques

There are a number of Encryption Techniques used commonly.

#### 3.3.1 Substitution cipher

In a *substitution cipher*, each letter or group of letters is directly replaced by another letter or group of letters which disguises it.

A well-known example of this is the Ceaser Cipher.

add example

Using a standard alphabet with 26 characters, assuming we only use lowercase letters, then there are  $4 \times 10^{26}$  possible combinations. Which on a computer with one million CPU cores - can take up to 10,000 years to crack.

### 3.3.2 Transposition Cipher

In a *transposition cipher*, we take a key and use this key to design a grid which we populate with our plaintext, working row-by-row. We then read the ciphertext from the grid reading column-by-column in alphabetical order of the key's letter.

add example. explanation in notes on slides

## 3.4 Symmetric Encryption

Symmetric Encryption is an encryption method in which the sender and receiver both use the same key to encode and decode the message. This is where it's alternative name, *shared key encryption* comes from.

Symmetric Encryption works through taking the plaintext input which is then encrypted using the key,  $K$ . The encryption algorithm will perform various substitutions or transformations on the plaintext, which will be key-dependent. This means that the same plaintext, with two different keys and the same encryption algorithm will produce two different ciphertexts. The ciphertext is then transmitted to the receiver. The receiver then decrypts the message using that pre-shared-key,  $K$ . The decryption algorithm is effectively the encryption algorithm run in reverse. This gives them the plaintext.

We can see an example of a Symmetric Encryption in the DES encryption method.

### 3.4.1 DES

The *Data Encryption Standard*, or DES, is a symmetric-key encryption algorithm which was developed in the 1970s and has been hugely influential in modern-day cryptography.

The plaintext input for DES is always 64-bits in length, and the key is always 56-bits. If the total plaintext needing to be encrypted using DES is longer than 64-bits then it gets chunked into 64-bit chunks so then the DES algorithm can process its 64-bit blocks.

The DES algorithm works by taking the 56-bit key and generating 16 sub-keys from it. These 16 sub-keys are each used for their own round of encryption, therefore the DES algorithm encrypts the plaintext 16 times through a sequence iterating on the output of the previous as the input to the next. The keys are used in reverse order - meaning  $K_{16}$  is used on the first iteration,  $K_{15}$  on the second, and so on until  $K_1$  is used on the final iteration.

Confirm level of detail required with Asim. Add examples and further explanation if needed.

### 3.4.2 3DES

The *Triple Data Encryption Standard*, or 3DES, is a symmetric-key encryption algorithm which applies the DES algorithm three times to each block.

3DES works with three keys,  $K_1$ ,  $K_2$ , and  $K_3$ . It will use  $K_1$  on the first round of DES encrypting the data. Then the second round of DES will decrypt the data using  $K_2$ . The third and final round of DES will encrypt the data using  $K_3$ . The middle decryption doesn't return the data to the plaintext state, as  $K_1 \neq K_2$ .

Decryption follows the same encryption process but in reverse: decrypting with  $K_3$ , encrypting with  $K_2$  before decrypting with  $K_1$ .

### 3.4.3 AES

The *Advanced Encryption Standard*, or AES, is a symmetric-key encryption algorithm which was designed to replace DES.

AES supports three different key lengths: 128-bit, 192-bit and 256-bit. Similarly to how DES works on 64-bits of data at a time, AES works on 128-bit blocks of data and will perform  $n$  rounds depending on the different key-length used. 128-bit keys get 10 rounds, 192-bit keys get 12 rounds and 256-bit keys get 14 rounds.

## 3.5 Asymmetric Encryption

Asymmetric Encryption is an encryption method where the sender and receiver both use different keys to encode and decode the message. This is where it's alternative name, *Public Key Encryption* comes from.

The sender encrypts the plaintext with the receivers public key to produce the ciphertext. The ciphertext is then transmitted over the network to the receiver. The receiver uses their private key to decrypt the message thus producing the plaintext.

The public key of the receiver is made available to anyone who wants to send the receiver a message. The public key of anyone is restricted to them and them alone - leaking of a public key would mean that a threat actor could decode the message. Due to the receivers public keys being required to be able to send the receiver a message - senders will have as many public keys as the number of people they send messages to.

A major flaw with this model is that a threat actor could intercept the public-key encoded message and stop it from reaching the receiver. Whilst they couldn't read that message, they could spoof that message by sending their own payload encoded with the receivers public key. The receiver would receive this and decode it.

We can see an example of the Asymmetric Encryption in the RSA algorithm.
